Abstract: Trichostrongylidae family is considered as a group of gastrointestinal nematodes of ruminants with widespread distribution in the world. The parasites are the major causes of productivity loss in many countries including Iran. This study was carried out to determine the distribution of abomasal Trichostrongylidae among livestock of Qazvin, Iran. Totally, 160 abomasum samples including 83 from sheep, 72 from cattle and 5 from goats were collected from slaughterhouses throughout the Qazvin Province. The ribosomal DNA internal transcribed spacer 2 (ITS2) region was amplified using PCR followed by sequencing 13 different isolates. Phylogenetic analysis of the identified sequences was performed using MEGA 7 software. The prevalence rate of the nematodes was 19.4\% among the specimens. Also, two spices including Marshallagia marshalli and Teladorsagia circumcincta were identified among the isolates with M. marshalli at higher frequency. No Trichostrongylus spp. was detected in the region. Since livestock plays a major role in ecosystem balance and as some species of nematodes have a zoonotic nature, it is necessary to proceed with more comprehensive epidemiologic studies to clarify the infection rate among the human population living in the region.

Keywords: Iran, ITS2-rDNA region, Phylogenetic analysis, Qazvin, Trichostrongylidae.

Introduction

The family of Trichostrongylidae is considered as the most important gastrointestinal parasites among sylvatic and domesticated ruminants with worldwide distribution (19, 38). Several species of the family were reported such as Teladorsagia circumcincta, Marshallagia marshalli and Trichostrongylus spp. (19, 33, 34, 38).

Human infection by Trichostrongylus spp. could occur by ingesting the infective-stage larvae or through skin penetration by larvae (14). Human infections are frequently free of apparent clinical symptoms, although gastrointestinal signs may occur in some patients (31, 39). The importance of veterinary medicine is not seriously taken into account and this has caused reduced production, economic losses, and public health concerns. These nematodes are considered as major causes of veterinary and zoonotic infections (12, 32). Differentiation and improved diagnosis between the species are necessary for control programs as effective control strategies can lead to positive effect over the economy of different countries (3).

Conventional methods based on morphological characters such as spicules, gubernaculum, and caudal bursa in male worms are reliable to detect the species nevertheless, these methods cannot discern the species of female worms (12, 31).

Molecular biology assays are applied for identification and phylogenetic analysis of different species of nematodes (38). Although several ribosomal and mitochondrial regions were used to survey the nematodes, investigating the ribosomal DNA sequencing (particularly the ITS2 region) has been shown to be a useful tool for this purpose as the ITS-2 gene region can clarify the intraspecific homogeneity and interspecific divergence of sequence in the species of gastrointestinal nematodes (5, 20, 31, 36).

It is well documented that Iranian researchers have a long term experience over examining the gastrointestinal nematodes among humans and animals by morphological features (2, 7, 11). Domestically, recent molecular analysis studies are limited to few investigations concerning the diagnosis of Trichostrongylus species,
without any data available for other species of the Trichostrongylidae family in the country (13, 30, 31). Due to lack of data on nematodes in the study region, the present research aimed at analyzing the morphological features as well as molecular characterization of ITS2 region of different species of the helminthes.

**Material and Methods**

**Sample collection and specimens examined:** Totally, 160 abomasum samples were collected from 83 sheep, 72 cattle and 5 goats during 2017-2018. The animals originated from Qazvin Province, located in northern margin of central Iran and were slaughtered at two local abattoirs of the cities of Qazvin and Takestan (Figure 1). This study was approved by the Medical Ethics Committee of Qazvin University of Medical Sciences (Approval code: IR.QUMS.REC.1396.375). All specimens were examined for infectivity by Trichostrongylidae family through washing the content of each abomasum by passing through 20, 40 and 100 mesh sieves and observed with stereomicroscope. The helminths were collected and cleaned with normal saline followed by addition of lactophenol to observe their morphological features. The specimens were preserved in 70% ethanol and kept at room temperature.

**DNA extraction and PCR assay:** Twenty female specimens were randomly selected for DNA extraction. The helminth was minced by 6 rounds of freeze-thaw cycles using 200 mg tissue lysis buffer and the finely minced worm was used the High Pure PCR Template Preparation Kit (Roche, Mannheim, Germany) for DNA extraction according to the manufacturer’s recommended protocol.

Fragments of ribosomal DNA internal transcribed spacer 2 (ITS2) region with approximately 328 bp was amplified with specific primers (30). Thirty microliter reaction volume containing 15 μl of PCR mix including Taq DNA polymerase, dNTPs and MgCl₂ (2 x Master Mix RED Ampliqon, Denmark), 11 μl of molecular biology grade water, 1 μl of each primer (10 pmol/μl) and 2 μl of DNA template was applied for each reaction. The PCRs were included the following temperatures, 94°C for 20 s (denaturation), 55°C for 20 s (annealing), 72°C for 30 s (extension) for 35 cycles and a final extension at 72°C for 5 min.

**Sequencing and phylogenetic analysis:** Following the purification (AccuPrep® PCR/Gel Purification Kit, Bioneer, Korea) of PCR products, each specimen was sequenced using Applied Biosystems ABI 3730xl DNA analyzer sequencing (Bioneer, Korea). The nucleotide sequences were compared with each other and with reference sequences using BioEdit software and adjusted manually (18). Multiple sequence alignment was made with the ClustalW method and further compared with the sequences present in the GenBank sequence database. Phylogenetic tree was constructed using Tamura 3-parameter model of ML (Maximum likelihood) method by the Molecular & Evolution Genetic Analysis software version 7 (MEGA 7.0). Bootstrap value was considered based on 1000 replications. *Necator americanus* sequence was considered as outgroup (Figure 2).

**Results**

Out of 160 specimens collected from sheep (51%), cattle (45%), and goats (3%) in the present study, 19.4% (31/160) samples were found to be infected with Trichostrongylidae. The prevalences of nematodes were 33.7% (28/83) and 60% (3/5) among sheep and goat, respectively. No infection was found in cattle specimens. Two species including *Marshallagia marshalli* and *Teladorsagia circumcincta* were identified among the isolates by morphological features which was later confirmed by molecular analysis (Figure 3). Infection rate of *M. marshalli* and *T. circumcincta* among sheep and goats are clarified in Table 1. None of *Trichostrongylus* spp. was detected in the study. A total of 13 ITS2-sequences of nematodes were deposited in GenBank, including ten *M. marshalli* (accession numbers: MK253683-MK253692) and three *T. circumcincta* (accession numbers: MK253693-MK253695). In addition,
the molecular survey demonstrated high similarity (more than 95%) between the sequences found in our study and those of *M. marshalli* and *T. circumcincta* in the GenBank sequence database.

A dendrogram based on the phylogenetic analysis revealed that morphological examination can detect the different species of the parasite (Figure 2). The isolates were grouped into two distinct clusters corresponding to the *M. marshalli* and *T. circumcincta* alongside the gene references. Multiple alignments represented that the intra-species similarity for *M. marshalli* and *T. circumcincta* were 98-100% and 100%, respectively.

**Discussion and Conclusion**

Trichostrongylid family is a group of significant parasites among sylvatic and domesticated ruminants and this makes the nematode infection as a common disease between the human and ruminant animals in endemic regions. Contamination by Trichostrongylid nematodes can cause permanent damage to livestock industry, leading to changes in animal body weight and decreased production output. The most frequent species of the family in ruminant are Nematodirus, Marshallagia, Haemonchus, Cooperia, Trichostrongylus and Teladorsagia (4, 6, 10, 21, 28).

The present study is the first report of the nematodes in Qazvin, Iran. This research revealed that the infection rate among sheep and goats were 33.7% and 60%, respectively. Several studies reported from Iran showed higher infection rate in livestock compared to that of the current research. Eslami et al. (7) reported an infection rate as 88% in sheep. Also, Borji et al. (2) described the presence of high infection rate (75.1%) by gastrointestinal helminths in camels. Mashayekhi et al. (25) found an infection rate equal to 44% among the abomasal nematodes of cattle. Unlike the research stated above, few studies have been reported lower infection rate in livestock (8, 27).

Based on morphological and molecular analysis, two species including *M. marshalli* and *T. circumcincta* were found among the domestic ruminants in Qazvin Province, Iran. *Marshallagia marshalli* was the most frequent species (90%), while *T. circumcincta* (9.7%) was less prevalent among the isolates. Aligned with our findings, the most commonly reported species among the livestock in different parts of the country was *M. marshalli* as claimed by Eslami et al. (7) who found *M. marshalli* (93%) and *T. circumcincta* (9.3%) among the wild sheep (*Ovis orientalis*). Borji et al. (2) has also reported *M. marshalli* and *T. circumcincta* in camel isolates in the northeast of Iran. Other studies carried out in different parts of Iran (including the southeastern, northwest, and central parts) determined isolation of the parasite species from sheep and goat (17, 23, 28, 35). Conversely, few...
studies have shown the higher frequency of *T. circumcincta* than *M. marshalli* in the ruminants. Nabavi et al. (27) found *T. circumcincta* at higher prevalence (19.3%) than *M. marshalli* (12.2%) in sheep isolates in the northern, central, and southern regions of Iran (Mazanderan, Isfahan and Khuzestan Provinces). Several studies have revealed the presence of *M. marshalli* and *T. circumcincta* among the ruminants in different parts of the world (5, 20, 26, 37).

Considering the extensive use of anti-parasitic drugs in the country, the main cause of high prevalence rate for nematodes is related to drug resistance emerged by the worms or might be due to decreased host immune response (15). The government strategic treatment of local livestock started since 1968 by administration of albendazole, twice a year for a duration of years (8), and subsequently, several species including *M. marshalli*, *T. circumcincta*, *T. colubriformis*, and *H. contortus* exhibited resistance to therapy (15, 28).

In domestic traditional animal husbandry throughout the country, the flocks of sheep and goats are kept and grazed together and this causes the persistence of the parasites in both types of farm animals (28), and the results of our study confirmed the presence of both *M. marshalli* and *T. circumcincta* species in different parts of the country, the flocks of sheep and goats are kept and grazed together and this causes the persistence of the parasites in both types of farm animals (28), and the results of our study confirmed the presence of both *M. marshalli* and *T. circumcincta* species in different parts of the country. In addition, it showed that *M. marshalli* is the predominant species among the local ruminants. The prevalence of nematodes could be related to the geographical condition, ecology, and the use of antiparasitic drugs.

The authors declared that there is no conflict of interests.
